

## Iterative methods

We've covered direct methods (LU for  $Ax = b$ , QR for  $\min \|Ax - b\|_2$ , QRalg for  $Ax = \lambda x$ ). These are

- ▶ Incredibly reliable, backward stable
- ▶ Works like magic if  $n \lesssim 10000$
- ▶ But not if  $n$  larger!

A 'big' matrix problem is one for which direct methods aren't feasible. Historically,

- ▶ 1950:  $n \geq 20$
  - ▶ 1965:  $n \geq 200$
  - ▶ 1980:  $n \geq 2000$
  - ▶ 1995:  $n \geq 20000$
  - ▶ 2010:  $n \geq 100000$
  - ▶ 2020:  $n \geq 1000000$  ( $n \geq 50000$  on a standard desktop)
- with super computers.*

was considered 'very large'. For such problems, we need to turn to alternative algorithms: we'll cover **iterative** and **randomised** methods.

# Direct vs. iterative methods

Idea of iterative methods:

- ▶ gradually refine solution iteratively
- ▶ each iteration should be (a lot) cheaper than direct methods, usually  $O(n^2)$  or less
- ▶ can be (but not always) much faster than direct methods
- ▶ tends to be (slightly) less robust, nontrivial/problem-dependent analysis
- ▶ often, after  $O(n^3)$  work it still gets the exact solution (ignoring roundoff errors)

image from [Trefethen-Bau]

We'll focus on **Krylov subspace methods**.

## Basic idea of Krylov: polynomial approximation

In Krylov subspace methods, we look for an (approximate) solution  $\hat{x}$  (for  $Ax = b$  or  $Ax = \lambda x$ ) of the form (after  $k$ th iteration)

$$\hat{x} = \underbrace{p_{k-1}(A)} v,$$

e.g.  $\hat{x} = \underbrace{A^2}_V = A(AV) \overset{\text{steps}}{\sim} \mathcal{O}(n^2)$   
 $(A^3 - \pi A + I) V$   
 $p_3(A) V$

where  $p_{k-1}$  is a **polynomial** of degree  $k-1$ , and  $v \in \mathbb{R}^n$  arbitrary (usually  $v = b$  for linsys, for eigenproblems  $v$  usually random)

Natural questions:

► Why would this be a good idea?

► Clearly, 'easy' to compute ✓

► One example: recall power method  $\hat{x} = \underbrace{A^{k-1} v}_{\text{specific poly for } Ax = \lambda x} = \underbrace{p_{k-1}(A)} v$

► Krylov finds a "better/optimal" polynomial  $\underbrace{p_{k-1}(A)}_{\|A^{k-1} v\|}$

► We'll see more cases where Krylov is powerful

► How to turn into an algorithm?

► Arnoldi (next), Lanczos

# Orthonormal basis for $\mathcal{K}_k(A, b)$

Find approximate solution  $\hat{x} = p_{k-1}(A)b$ , i.e. in **Krylov subspace**

$$\hat{\mathcal{K}} := \mathcal{K}_k(A, b) := \text{span}([b, Ab, A^2b, \dots, A^{k-1}b])$$

First step: form an orthonormal basis  $Q$ , s.t. solution can be written as  $x = Qy$   $y \in \mathbb{R}^k$

$P(A)b = \sum_{i=0}^{k-1} c_i A^i b = (c_{k-1} A^{k-1} b + c_{k-2} A^{k-2} b + \dots)$

► Naive idea: Form matrix  $[b, Ab, A^2b, \dots, A^{k-1}b]$ , then QR

- $[b, Ab, A^2b, \dots, A^{k-1}b]$  is usually terribly conditioned! Dominated by leading eigvec
- $Q$  is therefore extremely ill-conditioned, inaccurately computed

# Orthonormal basis for $\mathcal{K}_k(A, b)$

Find approximate solution  $\hat{x} = p_{k-1}(A)b$ , i.e. in **Krylov subspace**

$$\mathcal{K}_k(A, b) := \text{span}([b, Ab, A^2b, \dots, A^{k-1}b])$$

First step: form an orthonormal basis  $Q$ , s.t. solution can be written as  $x = Qy$

- ▶ Naive idea: Form matrix  $[b, Ab, A^2b, \dots, A^{k-1}b]$ , then QR
  - ▶  $[b, Ab, A^2b, \dots, A^{k-1}b]$  is usually terribly conditioned! Dominated by leading eigvec
  - ▶  $Q$  is therefore extremely ill-conditioned, inaccurately computed

- ▶ Much better solution: **Arnoldi process**
  - ▶ Multiply  $A$  once at a time to the latest orthonormal vector  $q_i$
  - ▶ Then orthogonalise  $Aq_i$  against previous  $q_j$ 's ( $j = 1, \dots, i-1$ ) (as in Gram-Schmidt)

Vanderkolk et al. (Arnoldi)  
[2021]

$$q_1 = \frac{b}{\|b\|} \quad q_2 = (Aq_1) - q_1 q_1^T (Aq_1)$$
$$q_2 = \frac{q_2}{\|q_2\|}$$
$$q_1, q_2 \in \text{span}(b, Ab)$$

then  $Aq_2 \in \text{span}(b, Ab, A^2b)$

$$q_3 = \frac{q_3}{\|q_3\|}$$
$$q_1, q_2, q_3 \in \text{span}(b, Ab, A^2b)$$
$$q_3 = (Aq_2) - q_1 q_1^T (Aq_2) - q_2 q_2^T (Aq_2)$$

# Arnoldi iteration

Set  $q_1 = b/\|b\|_2$

For  $k = 1, 2, \dots$ ,

set  $v = Aq_k$

for  $j = 1, 2, \dots, k$

$h_{jk} = q_j^T v$ ,  $v = v - h_{jk}q_j$  % orthogonalise against  $q_j$  via modified G-S

end for

$h_{k+1,k} = \|v\|_2$ ,  $q_{k+1} = v/h_{k+1,k}$

$$Q_j = [q_1 \dots q_j]$$

$$Q_k = [q_1 \dots q_k]$$

$$Q_{k+1} = [q_1 \dots q_k \ q_{k+1}]$$

End for

- ▶ After  $k$  steps,  $AQ_k = Q_{k+1}\tilde{H}_k = Q_k H_k + q_{k+1}[0, \dots, 0, h_{k+1,k}]$ , with  $Q_k = [q_1, q_2, \dots, q_k]$ ,  $Q_{k+1} = [Q_k, q_{k+1}]$ ,  $\text{span}(Q_k) = \text{span}([b, Ab, \dots, A^{k-1}b])$

$$\begin{array}{|c|} \hline A \\ \hline \end{array}
 \begin{array}{|c|} \hline Q_k \\ \hline \end{array}
 =
 \begin{array}{|c|} \hline Q_{k+1} \\ \hline \end{array}
 \begin{array}{|c|} \hline \tilde{H}_k \\ \hline \end{array},
 \quad
 \tilde{H}_k =
 \underbrace{\begin{bmatrix} h_{1,1} & h_{1,2} & \dots & h_{1,k} \\ h_{2,1} & h_{2,2} & \dots & h_{2,k} \\ & \ddots & & \vdots \\ 0 & & h_{k,k-1} & h_{k,k} \\ & & & h_{k+1,k} \end{bmatrix}}_{\mathbb{R}^{(k+1) \times k} \text{ upper Hessenberg}},
 \quad
 Q_{k+1}^T Q_{k+1} = I_{k+1}$$

$x = Q_k y = P_{k-1}(A)b.$

- ▶ Cost  $k$   $A$ -multiplications +  $O(k^2)$  inner products ( $O(nk^2)$ )

Lanczos iteration = Arnoldi when  $A = A^T$

When  $A$  symmetric, Arnoldi simplifies to

$$AQ_k = Q_k T_k + q_{k+1}[0, \dots, 0, h_{k+1,k}],$$

where  $T_k$  is **symmetric tridiagonal** (proof: just note  $H_k = Q_k^T A Q_k$  in Arnoldi)

$$\boxed{A} \boxed{Q_k} = \boxed{Q_{k+1}} \boxed{\tilde{T}_k}, \quad \tilde{T}_k = \underbrace{\begin{bmatrix} t_{1,1} & t_{1,2} & & & & \\ & t_{2,1} & t_{2,2} & & & \\ & & \ddots & & & \\ & & & \ddots & & \\ & & & & t_{k-1,k-1} & t_{k-1,k} \\ & & & & t_{k,k-1} & t_{k,k} \\ & & & & & t_{k+1,k} \end{bmatrix}}_{\mathbb{R}^{(k+1) \times k} \text{ symmetric tridiagonal}}, \quad Q_{k+1}^T Q_{k+1} = I_{k+1}$$

- ▶ 3-term recurrence, orthogonalisation necessary only against last two vecs  $q_k, q_{k-1}$
- ▶ Significant speedup over Arnoldi; cost  $k$   $A$ -mult. +  $O(k)$  inner products ( $O(nk)$ )
- ▶ In floating-point arithmetic, sometimes computed  $Q_k$  lose orthogonality and reorthogonalisation necessary (nonexaminable)

# The Lanczos algorithm for symmetric eigenproblem

**Rayleigh-Ritz:** given symmetric  $A$  and orthonormal  $Q$ , find approximate eigenpairs

1. Compute  $Q^T A Q \in \mathbb{R}^{k \times k}$  (boxed) hoped to "contain" eigvecs(A).
2. Eigenvalue decomposition  $Q^T A Q = V \hat{\Lambda} V^T$
3. Approximate eigenvalues  $\text{diag}(\hat{\Lambda})$  (Ritz values) and eigenvectors  $QV$  (Ritz vectors) (boxed)

This is a **projection** method (similar alg. available for SVD)

$Q_k = \mathcal{K}_k(A, b) = \text{span}[b, Ab, \dots, A^{k-1}b]$ .

**Lanczos algorithm = Lanczos iteration + Rayleigh-Ritz**

- ▶ In this case  $Q = Q_k$ , so simply  $Q_k^T A Q_k = T_k$  (tridiagonal eigenproblem)
- ▶ Very good convergence to extremal eigenpairs

▶ Recall from Courant-Fisher  $\lambda_{\max}(A) = \max_x \frac{x^T A x}{x^T x}$  Rayleigh quotient.

▶ Hence  $\lambda_{\max}(A) \geq \underbrace{\max_{x \in \mathcal{K}_k(A, b)} \frac{x^T A x}{x^T x}}_{\text{Lanczos output}} \geq \underbrace{\frac{v^T A v}{v^T v}}_{\text{power method}}, \quad v = A^{k-1} b$

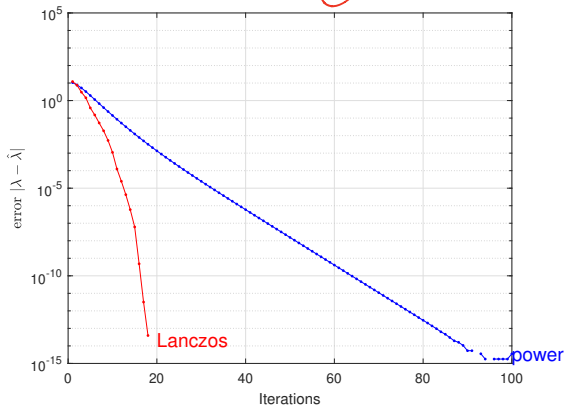

▶ Same for  $\lambda_{\min}$ , similar for e.g.  $\lambda_2$

$x = Qy$   $\max_y \frac{y^T Q^T A Q y}{y^T Q^T Q y} = \lambda_{\max}(Q^T A Q) = \text{largest Ritz val!}$   
 $= y^T y$

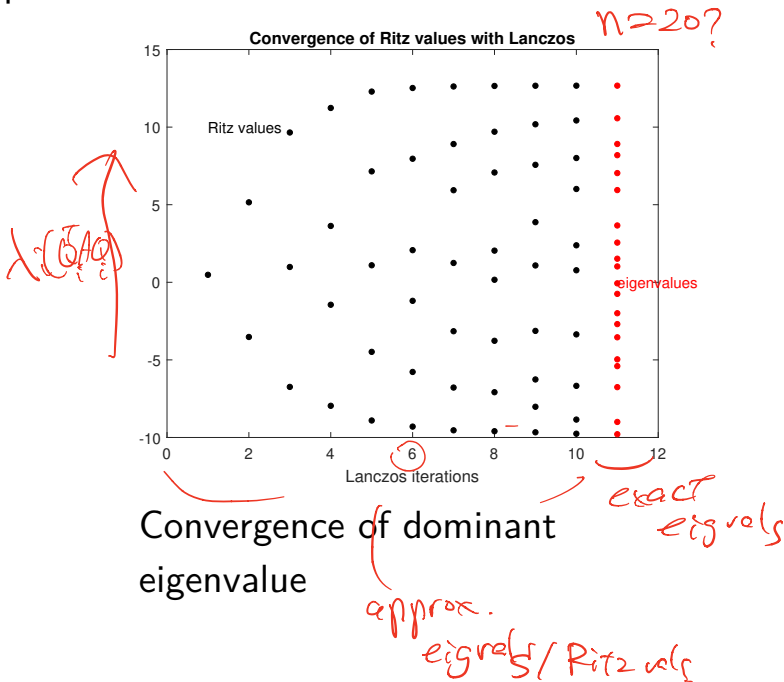

# Experiments with Lanczos

Symmetric  $A \in \mathbb{R}^{n \times n}$ ,  $n = 100$ , Lanczos/power method with random initial vector  $b$

Convergence to dominant eigenvalue

Convergence of dominant eigenvalue

approx. eigvals / Ritz vals
